PACS 04A25

We present infrared and millimeter observations of molecular gas, dust and ionized gas towards a sample of clouds distributed along the 500 central pc of the Galaxy. The clouds were selected to investigate the physical state, in particular the high gas temperatures, of the Galactic center region (GCr) clouds located far from far-infrared of thermal radio continuum sources. We have found that there is ionized gas associated with the molecular gas. The ionizing radiation is hard (~ 35000 K) but diluted due to the inhomogeneity of the medium. We estimate that $\sim 30\%$ of the warm molecular gas observed in the GCr clouds is heated by ultra-violet radiation in photo-dissociation regions.

1 Introduction

The interstellar medium in the 500 central pc of the Galaxy (hereafter Galactic Center region, GCr) is mainly molecular. The molecular clouds in the GCr exhibit an extended gas component with high temperature (150 K). On the contrary, the dust temperature is lower than ~ 30 K. The large line widths of the molecular lines, the high gas phase abundance of molecules linked to the dust chemistry, and the difference between gas and dust temperature suggest that some kind of shocks could be responsible for the high gas temperatures of the molecular gas (Wilson et al. 1982, Martín-Pintado et al. 2001). The possible influence of radiation in the heating of the molecular gas is also usually ruled out due to the lack of far infrared and thermal radio continuum sources in the GCr others than the well known H II regions associated to the Sgr complexes (A, B,...) or ionized nebulae like the Sickle.

To investigate the heating of the molecular clouds in the GCr we have studied a sample of 18 clouds located all along this region. The clouds were selected as molecular peaks located far from far infrared or radio continuum sources. Those sources were observed with the spectrometers on board the *Infrared Space Observatory* (ISO) and with the IRAM 30-m telescope. The data obtained with ISO are observations of the lowest H₂ pure-rotational lines, dust continuum spectra from 40 to 190 μ m and a number of fine-structure lines from neutral atoms or ions (O I 63 μ m, C II 158 μ m, Ne II 12 μ m, O III 52 μ m ...). With the IRAM 30-m antenna we have observed C¹⁸O, ¹³CO, H35 α and H41 α .

In these paper we will review the results already published in Rodríguez-Fernández et al. (2001a, 2001b, hereafter RF01a, RF01b, respectively) and we will present some new results that will be extended elsewhere (Rodríguez-Fernández et al. 2003, RF03).

2 Warm molecular gas

Before ISO, the warm gas component of the GCr molecular clouds was mainly studied by means of NH_3 observations. The multilevel study of Huttemeister et al. (1993) showed that the temperature structure of the GCr clouds can be characterized with two gas components at different temperatures: a cold gas component with a temperature close to that of the dust (~ 20 K) and a warm gas component whose temperature ranges from 100 to 250 K. However, since the abundance of ammonia is known to vary significantly it is difficult to estimate the column density of warm gas in the GCr clouds. We have, for the first time, obtained the column density of warm gas in the GCr clouds by observing H_2 pure rotational lines (RF01a). Columns 3 and 4 of Table 1 show the total column density and the temperature of the warm gas, respectively. We have also estimated the H_2 density and the total column density of molecular gas in this clouds by observing ^{13}CO and C^{18}O and doing a radiative transfer analysis for kinetic temperatures between 15 and 200 K. The results are shown in columns 1 and 2 of Table 1. The fraction of warm H_2 to the total H_2 column density as traced by CO varies from source to source but it is of 30% on average.

As discussed in RF01a, it is difficult to explain the large column density of warm gas in the GCr clouds. Several low velocity ($\sim 10 \text{ Km s}^{-1}$) C-shocks, photo-dissociation regions (PDRs) or both should be present in the line of sight. Comparing the energy of the turbulent motions in the GCr clouds with the cooling by H_2 (which at the moderate density of the GCr clouds is comparable to that by CO), one finds that dissipation of supersonic turbulence could account for the heating of the warm H_2 . However, with the available data is not possible to rule out heating in PDRs, indeed the observed temperature gradient in the GCr clouds can be appropriately reproduced in a context of a PDR (RF01a).

3 Dust temperatures

The dust continuum emission peaks at wavelengths of 100 to $80 \mu\text{m}$ for all but two sources, whose spectra peaks at $50\text{-}60 \mu\text{m}$. The dust luminosity in the observed range is listed in column 5 of Table 1. It is not possible to fit the spectra with just one grey body. Thus we have used a model with two grey bodies like that described in section 2 of Goicoechea et al. (2003). Figure 1 shows the data and the grey bodies fits for two sources. To explain the emission at long wavelengths it is needed a dust component with a temperature of 15 to 18 K. The temperature of the warmer component varies from source to source from 26 to 39 K. Due to the uncertainties in the dust emissivity it is not easy to determine a total column density of dust (on the contrary, temperatures are almost independent on the dust emissivity). Nevertheless, the column density of dust with temperatures higher than 50 K is less than 500 times lower than the column of dust at 15-35 K.

Fig. 1 Left panel: Dust continuum emission towards M+0.21-0.12 (black solid triangles) and grey-body fit (green) with two temperature components at 39 (red) and 16 K (blue). Right panel: same for M+0.76-0.05 with a 24 K (red) and 15 K (blue) components.

Table 1 Physical parameters derived from the observations. See text for explanation. Number in parentheses are errors of the last significant digit. Typical errors of T_1 and T_2 are 5 and 1 K, respectively.

4 Radio recombination lines

To study the possible presence of ionized gas associated with the GCr molecular clouds we have observed the $H41\alpha$ and $H35\alpha$ recombination lines using the IRAM 30m antenna (RF03). However, we have not detected any of the lines in any of the sources. From our 3σ limits to the line fluxes we have determined upper limits to the flux of Lyman continuum photons in the 30m beam (column 8 of Table 1). The comparison of those limits with stellar atmospheres models rules out the presence of stars of an earlier type than B0.5 and effective temperatures higher than ~ 32000 K.

5 Fine structure lines

We have detected lines of atoms and low excitational potential (< 13.6 eV) ions like O I $63 \mu\text{m}$, C II $158 \mu\text{m}$ or Si II $34 \mu\text{m}$ in all of the sources. In most of them we have also detected N II $122 \mu\text{m}$ or Ne II $12 \mu\text{m}$ (excitational potential of 14 and 21 eV respectively). In 11 of the 18 sources we have even detected the O III $88 \mu\text{m}$ line (the excitational potential of O III is 35 eV). Column 9 of Table 1 shows the electron densities of the ionized gas component as derived from the O III 52 to O III $88 \mu\text{m}$ lines ratios. The densities, around $10\text{-}100 \text{ cm}^{-3}$, are lower than those found in the Radio Arc region (RF01b) and in Sgr B2 (Goicoechea et al. 2003). Column 10 of Table 1 shows the effective temperatures derived from the N III $57 \mu\text{m}$ to N II $122 \mu\text{m}$ lines ratios for the three sources where the N III line has been detected. These

temperatures have been calculated following the H II regions models by Rubin et al (1994). However, as pointed out by Shields and Ferland (1994) the observed lines ratios can even be reproduced with higher effective temperatures of the ionizing radiation if the ionization parameter is low, i.e., if the medium is clumpy and inhomogeneous and the ionizing sources are located far from the ionized nebulae. These seems to be the case of the Radio Arc region, where we have shown the presence of an extended component of gas ionized by the combined effect of the Quintuplet and the Arches clusters (RF01b). The radiation can reach large distances due to the inhomogeneity of the medium (in part due to the presence of a large bubble clearly seen in infrared images). Fotoionization model calculations showed that the lines ratios observed in this region can be explained with a constant effective temperature of the ionizing radiation but a different ionization parameter for each cloud consistently with the different distances of the clouds to the ionizing sources.

The analysis is more difficult for the clouds located far from the Radio Arc region since the geometry of the medium and the possible ionizing sources are unknown. However, fotoionization simulations for many lines ratios demonstrate that effective temperatures of ~ 35000 K are possible if the ionization parameter is low ($\sim 10^{-3}$, RF03).

Some of the fine structure lines have been observed in the Fabry-Perot mode. The spectral resolution of this mode ($\sim 30 \text{ km s}^{-1}$) give us the possibility of studying the line profiles of the broad GCr lines. Figure 2 shows a sample of the lines observed in this mode towards two sources. Taking into account the moderate spectral resolution, the lines profiles and the lines centers of highly excited ions like O III are in good agreement with those of the neutral or low excitational potential ions like (O I and C II). Furthermore, Fig. 3 shows that the agreement of the line profiles of the weakly ionized gas and the molecular gas is rather good. This fact suggest that the three components are associated and that radiation could play a role not only in the ionization of the ionized gas but also in the heating of the neutral gas.

We have compared the observed far infrared continuum and the C II, O I and Si II lines fluxes with the predictions from PDR models. The power radiated by lines is $\sim 0.5\%$ of that radiated by the continuum. While the C II/O I ratio is ~ 5 . Plotting both quantities in a plot like that of Fig. 2d of Goicoechea et al. (2003), one finds that the GCr clouds exhibit similar properties to those of Sgr B2, with a far ultra-violet field $\sim 10^3$ times larger than the local interstellar radiation field and a hydrogen density of $\sim 10^3 \text{ cm}^{-3}$. The absolute fluxes of the C II ($\sim 10^{-17} \text{ W cm}^{-2}$) and the O I line ($\sim 2 \cdot 10^{-18} \text{ W cm}^{-2}$) are also consistent with the Hollenbach et al. (1991) PDRs models predictions.

6 Discussion: heating and ionization

The IRAM-30m “radio view” of the GCr interstellar medium seems to confirm the “classical” idea of a mainly neutral and dense gas. However, the global picture arising from the ISO observations is a complex interstellar medium with associated molecular, atomic, and ionized gas components with decreasing densities ($n_{\text{H}_2} \sim 10^4, n_{\text{H}} \sim 10^3, n_e \sim 10^{1-2} \text{ cm}^{-3}$). The ionizing radiation is hard (effective temperatures close to ~ 35000 K) but diluted due to the large distances from the ionizing sources to the nebulae (~ 50 pc in the Radio Arc region). The large distance effect of the ionizing radiation can only be explained if the interstellar medium is very inhomogeneous. This scenario is also necessary to explain the low number of Lyman continuum photons derived from the radio recombination lines observations.

The radiation must also influence the atomic and molecular phases. As we have seen, the O I and C II lines are well explained by a PDR with a H density of $\sim 10^3 \text{ cm}^{-3}$ and a far ultra-violet incident field 10^3 times higher than that in the local interstellar medium. The absolute O I and C II lines fluxes predicted by the PDR models are also similar the observed fluxes arising from the GCr clouds. Those models also predict a warm H_2 layer with temperatures of ~ 150 K, as we have derived from the pure-rotational lines. However, the total column density of warm H_2 predicted by the models is $\sim 3 \cdot 10^{21} \text{ cm}^{-2}$ while the total column density of warm H_2 that we have derived from the pure-rotational lines is $\sim 10^{22} \text{ cm}^{-2}$. Thus,

Fig. 2 Fabry-Perot spectra

Fig. 3 A comparison of the line profiles of $^{13}\text{CO}(1-0)$ (green) and C II 158 μm (blue) towards M+0.24+0.02 (up) and M+0.58-0.13 (down). Intensity in arbitrary units.

we conclude that approximately 30 % of the warm molecular gas in the GCr clouds arises in PDRs in the external layers of the clouds.

It is important to note that the discrepancy of dust and gas temperatures only rules out gas heating by gas collisions with hot dust, but it does not rule out *all* radiative heating mechanisms. In the external layers of the proposed PDRs the gas is heated to temperatures of ~ 150 K by photo-electric effect on the dust grains without heating the dust to temperatures higher than ~ 35 K (Hollenbach et al. 1991). In fact, the ~ 30 K dust component in the GCr can be associated to the 150 K gas.

At least a fraction of the other 70 % of warm gas should be heated by shocks. The main evidence for shocks in the GCr are the high degree of turbulence revealed by the large line-widths and the high abundance in gas phase of molecules linked to the dust chemistry as SiO, NH_3 or $\text{C}_2\text{H}_5\text{OH}$ (Martín-Pintado et al. 2001), which are easily photo-dissociated in the presence of ultra-violet radiation.
